# Mathematical foundations of Machine Learning 2024 - lesson 6 

## Shai Dekel

TEL AVIV UNIVERSITY

## The role of deep learning

- Good separability in input feature space $\rightarrow$ classical ML models are sufficient
- Logistic Regression, Support Vector Machines, Random Forest, Gradient Boosting, etc.
- If not, can we transform to a better feature space through feature engineering/deep learning?

MNIST DATASET

## Deep Learning building blocks

## Convolutions

Assignment: The convolution of $f, g \in L_{1}\left(\mathbb{R}^{n}\right)$ is defined by $f * g(x):=\int_{\mathbb{R}^{n}} f(x-y) g(y) d y$.
(i) Prove that $f * g \in L_{1}\left(\mathbb{R}^{n}\right)$,
(ii) Prove that $f * g=g * f$,
(iii) With the Fourier Transform defined by $\hat{f}(w)=\int_{\mathbb{R}^{n}} f(x) e^{-i\langle\psi, x\rangle} d x$, for $w \in \mathbb{R}^{n}$, show that

$$
(f * g)^{\wedge}(w)=\hat{f}(w) \hat{g}(w), \quad \forall w \in \mathbb{R}^{n} .
$$

(iv) Let $f \in L_{1}\left(\mathbb{R}^{2}\right)$ be a piecewise constant function. Design a 'filter' $g \in L_{\infty}\left(\mathbb{R}^{2}\right)$, with support in $[-\varepsilon / 2, \varepsilon / 2]^{2}$, for some $\varepsilon>0$, such that $f * g$ is 'significant' only in $\varepsilon$ neighborhoods of points where $f$ has 'almost' vertical edges.

## Discrete convolutions

1D discrete filter $g:=\left\{g_{k}\right\}_{k=-M}^{M}$. The filter size is $2 M+1$. Let $f=\left\{f_{j}\right\}_{j=-\infty}^{\infty}$. The discrete convolution is

$$
f * g(k):=\sum_{j=-\infty}^{\infty} f_{j} g_{k-j} .
$$

## Examples:

1. Smooth convolution, low-pass filter $g=\left(g_{-1}, g_{0}, g_{1}\right)=\left[\frac{1}{4}, \frac{1}{2}, \frac{1}{4}\right]$.
2. High-pass filter $g=\left(g_{-1}, g_{0}, g_{1}\right)=\left[-\frac{1}{4}, \frac{1}{2},-\frac{1}{4}\right]$. It has two vanishing moments:
a. If $f_{j}=c, \forall j, f * g(k)=-\frac{1}{4} c+\frac{1}{2} c-\frac{1}{4} c=0$,
b. If $f_{j}=a j+b, f * g(k)=-\frac{1}{4}(a(k-1)+b)+\frac{1}{2}(a k+b)-\frac{1}{4}(a(k+1)+b)=0$.

It is designed to detect 'jumps'

## Discrete convolutions

ode : \{'full', 'valid', 'same'\}, optional
'full':
By default, mode is 'full'. This returns the convolution at each point of overlap, with an output shape of ( $\mathrm{N}+\mathrm{M}-1$, ). At the end-points of the convolution, the signals do not overlap completely, and boundary effects may be seen.
'same':
Mode 'same' returns output of length max (M, N).
Boundary effects are still visible.
data = np.load("example_data.npy")
kernel_size $=10$
kernel = np.ones(kernel_size) / kernel_size
data_convolved = np.convolve(data, kernel, mode='same')
valid':
Mode 'valid' returns output of length max (M, N) $\min (M, N)+1$. The convolution product is only given for points where the signals overlap completely. Values outside the signal boundary have no effect.

## Discrete convolutions

2D discrete filter $g:=\left\{g_{k_{1}, k_{2}}\right\}_{k_{1}, k_{2}=-M}^{M}$. Filter size is $(2 M+1)^{2}$. Let $f=\left\{f_{j}\right\}_{j \in \mathbb{Z}^{2}}$. The discrete convolution is

$$
f * g(k)=f * g\left(k_{1}, k_{2}\right):=\sum_{j \in \mathbb{Z}^{2}} f_{j} g_{k-j} .
$$

Example Smooth convolution, low-pass filter

$$
g=\left[\begin{array}{ccc}
\frac{1}{16} & \frac{1}{8} & \frac{1}{16} \\
\frac{1}{8} & \frac{1}{4} & \frac{1}{8} \\
\frac{1}{16} & \frac{1}{8} & \frac{1}{16}
\end{array}\right]
$$

## Discrete convolutions

One can decompose a symmetric 2D filter through a tensor decomposition using two 1D filters $\tilde{g}_{1}, \tilde{g}_{2}$

$$
f * g\left(k_{1}, k_{2}\right)=\left[\left[f\left(\cdot, k_{2}\right) * \tilde{g}_{1}\right]\left(k_{1} \cdot \cdot\right) * \tilde{g}_{2}\right]\left(k_{1}, k_{2}\right)
$$

Example $\tilde{g}_{1}=\tilde{g}_{2}=\tilde{g}=\left(\tilde{g}_{-1}, \tilde{g}_{0}, \tilde{g}_{1}\right)=\left[\frac{1}{4}, \frac{1}{2}, \frac{1}{4}\right]$

$$
\begin{aligned}
f * g\left(k_{1}, k_{2}\right)= & \frac{1}{4}\left(\frac{1}{4} f_{k_{1}-1, k_{2}-1}+\frac{1}{2} f_{k_{1}-1, k_{2}}+\frac{1}{4} f_{k_{1}-1, k_{2}+1}\right) \\
& +\frac{1}{2}\left(\frac{1}{4} f_{k_{1}, k_{2}-1}+\frac{1}{2} f_{k_{1}, k_{2}}+\frac{1}{4} f_{k_{1}, k_{2}+1}\right) \\
& +\frac{1}{4}\left(\frac{1}{4} f_{k_{1}+1, k_{2}-1}+\frac{1}{2} f_{k_{1}+1, k_{2}}+\frac{1}{4} f_{k_{1}+1, k_{2}+1}\right)
\end{aligned}
$$

## Zero padding for a $3 \times 3$ filter

| 0 | 0 | 0 | 0 | 0 | 0 | 0 | 0 | 0 | 0 |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| 0 | $x_{00}$ | $x_{01}$ | $x_{02}$ | $x_{03}$ | $x_{04}$ | 0 |  | 0 | $x_{00}$ |
| 0 | $x_{10}$ | $x_{11}$ | $x_{12}$ | $x_{13}$ | $x_{14}$ | 0 |  |  | $x_{10}$ |
|  | $x_{11}$ |  |  |  |  |  |  |  |  |
| 0 | $x_{20}$ | $x_{21}$ | $x_{22}$ | $x_{23}$ | $x_{24}$ | 0 |  |  |  |
| 0 | $x_{30}$ | $x_{31}$ | $x_{32}$ | $x_{33}$ | $x_{34}$ | 0 |  |  |  |
| 0 | $x_{40}$ | $x_{41}$ | $x_{42}$ | $x_{43}$ | $x_{44}$ | 0 | $x_{11}$ | $x_{12}$ | $x_{13}$ |
| 0 | 0 | 0 | 0 | 0 | 0 | 0 | $x_{21}$ | $x_{22}$ | $x_{23}$ |

## Mirror/reflection padding for a $3 \times 3$ filter

| 3 | 5 | 1 |
| :--- | :--- | :--- |
| 3 | 6 | 1 |
| 4 | 7 | 9 |

| 1 | 6 | 3 | 6 | 1 | 6 | 3 |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| 1 | 5 | 3 | 5 | 1 | 5 | 3 |
| 1 | 6 | 3 | 6 | 1 | 6 | 3 |
| 9 | 7 | 4 | 7 | 9 | 7 | 4 |
| 1 | 6 | 3 | 6 | 1 | 6 | 3 |

## Classic convolutions - Curvelets

- Curvelets: a 2d "stable basis" designed to capture edge singularities
- Each element is associated with: location, frequency, directionality
- Coefficients of curvelets not located "on" or not aligned with edge singularity are "insignificant"

## Curvelets - construction via tiling in Fourier domain

Figure 1: Curvelet tiling of space and frequency. The figure on the left represents the induced tiling of the frequency plane. In Fourier space, curvelets are supported near a "parabolic" wedge, and the shaded area represents such a generic wedge. The figure on the right schematically represents the spatial Cartesian grid associated with a given scale and orientation.

## Classic convolutions - Curvelets

Figure 10: Curvelets at increasingly fine scales. The left panels represent curvelets (real part) in the spatial domain (as functions of the spatial variable $x$ ). The right panels show the modulus of the Fourier transform (as functions of the frequency variable $\omega$ ). The color map is the same as in Figure 9.

## Convolutions - through learning

- Convolution filters of first layer in a computer vision deep learning network: learning of edge \& color detectors
- The coefficients of the filters are part of the "weights" of the network.

## Learning filter decomposition

A trained "convolutional pipeline" for 14 unknowns, instead of 49...

Figure 5. The schema for $17 \times 17$ grid modules of the pure Inception-v4 network. This is the Inception-B block of Figure 9

## 3D discrete convolutions

In computer vision architectures, we typically need 3d convolutions in the inner layers: $x, y$ and $z$ is the feature map (channel) dimensions

$$
f * g(k)=f * g\left(k_{1}, k_{2}, k_{3}\right):=\sum_{j \in \mathbb{Z}^{3}} f_{j} g_{k-j} .
$$

The filter is typically localized in the $x, y$ direction, but not in the $z$ direction.

128 filters, each of dimension $3 \times 3 \times 192$

## Fully connected (dense) layers

Definition Let $M \in M_{n \times m}$ be a nonsingular matrix and $b \in \mathbb{R}^{m}$ a (bias) vector. The associated affine transform $A: \mathbb{R}^{n} \rightarrow \mathbb{R}^{m}$, is defined by $A x=M x+b, \forall x \in \mathbb{R}^{n}$.

Fully connected layer - every input vector element potentially contributes to any output vector element $x_{\text {out }}=A x_{\text {in }}=M x_{\text {in }}+b$.

Remark A Conv layer is a special case of a FC layer! allows to significantly reduce the number of (unknown) weights, based on the assumption of locality, i.e. the output (neurons) have a localization property, they are associated with visual elements in a certain neighborhood (whose support grows with the depth of the layers). So, they should only be affected by inputs in a certain neighborhood.

## Non-linearities

A decomposition of affine transforms is an affine transform

$$
A_{2}\left(A_{1} x\right)=M_{2}\left(A_{1} x\right)+b_{2}=M_{2}\left(M_{1} x+b_{1}\right)+b_{2}=\left(M_{2} M_{1}\right) x+\left(M_{2} b_{1}+b_{2}\right) .
$$

So, without any other functionality, a neural network essentially collapses into one affine transform.

## Typical non-linearities

$$
\tanh (x)=\frac{\sinh (x)}{\cosh (x)}=\frac{\frac{e^{x}-e^{-x}}{2}}{\frac{e^{x}+e^{-x}}{2}}=\frac{e^{x}-e^{-x}}{e^{x}+e^{-x}}
$$

ReLU (Rectifier Linear Unit)

$$
f(x)=\tanh (x)
$$

## Applying non-linearities

Typically, non-linearities are applied pointwise after the affine operations (Conv or FC). So, if $\sigma(y):=\left(\operatorname{ReLU}\left(y_{1}\right), \ldots, \operatorname{ReLU}\left(y_{m}\right)\right)$. A complete FC layer is then $\sigma(A(x))=\sigma(M x+b)$.

Non-linearities can be explained in two ways:

1. Neural Sciences approach - Simulation of neuron activation
2. Approximation-theoretical explanation of ReLu - The entire NN can be viewed as a continuous piecewise linear approximation over the original feature space. Why? Over sub-domains of the original feature subspace, the NN collapses into one local affine transform.
1

NN as piecewise linear approximation over the input space

Figure 1. How many linear regions? This figure shows a twodimensional slice through the 784-dimensional input space of vectorized MNIST, as represented by a fully-connected ReLU network with three hidden layers of width 64 each. Colors denote different linear regions of the piecewise linear network.

## Dimension reduction operations

Typically applied after the non-linearities in encoder architectures used for classification

## Pytorch image CIFAR classification example

For this tutorial, we will use the CIFAR10 dataset. It has the classes: 'airplane', 'automobile', 'bird', 'cat', 'deer', 'dog', 'frog', 'horse', 'ship', 'truck'. The images in CIFAR-10 are of size $3 \times 32 \times 32$, i.e. 3 -channel color images of $32 \times 32$ pixels in size.

## Pytorch image CIFAR classification example

```
import torch.nn as nn
import torch.nn.functional as F
```

```
class Net(nn.Module):
    def __init__(self):
        super().__init__()
        self.conv1 = nn.Conv2d(3, 6, 5)
        CLASS torch.nn.Conv2d(in_channels, out_channels, kernel_size, stride=1, padding=0, dilation=1,
        self.conv1 = nn.Conv2d(3, 6, 5)
        self.conv2 = nn.Conv2d(6, 16, 5)
/groups=1, bias=True, padding_mode='zeros', device=None,dtype=None)/[SOURCE]
        self.fc1 = nn.Linear(16 * 5 * 5, 120)
        self.fc2 = nn.Linear(120, 84)
        self.fc3 = nn.Linear(84, 10)
    def forward(self, x):
        x = self.pool(F.relu(self.conv1(x)))
        x = self.pool(F.relu(self.conv2(x)))
        x = torch.flatten(x, 1) 非 flatten all dimensions except batch
        x = F.relu(self.fc1(x))
        x = F.relu(self.fc2(x))
        x = self.fc3(x)
        return x
        Layer Dimensions:
    Layer 0-3x32x32
    Layer 1-6\times28\times28 (pooling) -> 6x14\times14
    Layer 2-16x10x10 (pooling) -> 16x5x5
    Layek 3-120
    Layer 4 84

    Layer 4->5 - 840+10=850
net = Net()
```

## Pytorch image CIFAR classification example

$x=\left(x_{1}, \ldots, x_{10}\right)$ is the representation at the last layer

$$
\operatorname{Pr}\left(y=Y_{k} \mid x\right):=\frac{e^{-x(k)}}{\sum_{j=1}^{10} e^{-x(j)}}
$$

$$
-\frac{1}{\# I} \sum_{i \in I} \log \left(\operatorname{Pr}\left(Y=y_{i} \mid x_{i}\right)\right)
$$

```
import torch.optim as optim
```

criterion $=$ nn.CrossEntropyLoss()
optimizer $=$ optim.SGD(net.parameters(), lr=0.001, momentum=0.9)

## Pytorch image CIFAR classification example

```
for epoch in range(2): 非 loop over the dataset multiple times
    running_loss = 0.0
    for i, data in enumerate(trainloader, 0):
    # get the inputs; data is a list of [inputs, labels]
    inputs, labels = data
    # zero the parameter gradients
    optimizer.zero_grad()
    # forward + backward + optimize
    outputs = net(inputs)
    loss = criterion(outputs, labels)
    loss.backward()
    optimizer.step()
    # print statistics
    running_loss += loss.item()
    if i % 2000 == 1999: 非 print every 2000 mini-batches
        print(f'[{epoch + 1}, {i + 1:5d}] loss: {running_loss / 2000:.3f}')
        running_loss = 0.0
```

print('Finished Training')

## IM여GENET

ImageNet is an image database organized according to the WordNet hierarchy (currently only the nouns), in which each node of the hierarchy is depicted by hundreds and thousands of images. Currently we have an average of over five hundred images per node. We hope ImageNet will become a useful resource for researchers, educators, students and all of you who share our passion for pictures. Click here to learn more about ImageNet, Click here to join the ImageNet mailing list.

Computer Vision - ECCV 2014 (ECCV 2014)

Fig. 3. Architecture of our 8 layer convnet model. A 224 by 224 crop of an image (with 3 color planes) is presented as the input. This is convolved with 96 different 1st layer filters (red), each of size 7 by 7 , using a stride of 2 in both $x$ and $y$. The resulting feature maps are then: (i) passed through a rectified linear function (not shown), (ii) pooled (max within $3 x 3$ regions, using stride 2) and (iii) contrast normalized across feature maps to give 96 different 55 by 55 element feature maps. Similar operations are repeated in layers $2,3,4,5$. The last two layers are fully connected, taking features from the top convolutional layer as input in vector form (6•6•256=9216 dimensions). The final layer is a $C$-way softmax function, $C$ being the number of classes. All filters and feature maps are square in shape.

## 3 Training Details

We now describe the large convnet model that will be visualized in Section 4. The architecture, shown in Fig. 3, is similar to that used by Krizhevsky et al. [18] for ImageNet classification. One difference is that the sparse connections used in Krizhevsky's layers $3,4,5$ (due to the model being split across 2 GPUs) are replaced with dense connections in our model. Other important differences relating to layers 1 and 2 were made following inspection of the visualizations in Fig. 5, as described in Section 4.1.

The model was trained on the ImageNet 2012 training set (1.3 million images, spread over 1000 different classes) [6]. Each RGB image was preprocessed by resizing the smallest dimension to 256 , cropping the center $256 \times 256$ region, subtracting the per-pixel mean (across all images) and then using 10 different sub-crops of size $224 \times 224$ (corners + center with(out) horizontal flips). Stochastic gradient descent with a mini-batch size of 128 was used to update the parameters, starting with a learning rate of $10^{-2}$, in conjunction with a momentum term of 0.9 . We

Feature Visualization: Fig. 2 shows feature visualizations from our model once training is complete. For a given feature map, we show the top 9 activations, each projected separately down to pixel space, revealing the different
structures that excite that map and showing its invariance to input deformations. Alongside these visualizations we show the corresponding image patches. These have greater variation than visualizations which solely focus on the discriminant structure within each patch. For example, in layer 5, row 1, col 2, the patches

## Layer 1

## Simple loss functions and backpropagation

## Regression loss functions

$\tilde{f}(x)$ is the output of the network. It needs to be piecewise smooth. So the building blocks of the network need to be piecewise smooth.
For example, the max-pooling operation $\max \left(f_{1}(x), \ldots, f_{M}(x)\right)$ of smooth functions $\left\{f_{1}, \ldots, f_{M}\right\}$, is piecewise smooth.
$\begin{array}{ll}\text { Mean Squared Error (MSE) } & \frac{1}{\# I_{\text {train }}} \sum_{i \in I_{\text {trin }}}\left(\tilde{f}\left(x_{i}\right)-y_{i}\right)^{2} \\ \text { Mean Averaged Error (MAE) } & \frac{1}{\# I_{\text {train }}} \sum_{i \in I_{\text {train }}}\left|\tilde{f}\left(x_{i}\right)-y_{i}\right|^{\text {Piecewise }}\end{array}$

## Backpropagation

Assume a model with one weight $f(x)=f(x, w)$. Assume loss is $L(w)=\sum_{i}\left(f\left(x_{i}, w\right)-y_{i}\right)^{2}$
Minimization is performed using gradient descent. Start with an initial (random) guess $w^{(0)}$. At each step $k$ compute for a certain subset $\Lambda^{(k)}$ of the training dataset

$$
\begin{aligned}
\left.\frac{d}{d w} L\right|_{w^{(k)}} & =2 \sum_{i \in \Lambda^{(k)}}\left(f\left(x_{i}, w^{(k)}\right)-y_{i}\right) \frac{\partial f\left(x_{i}, w^{(k)}\right)}{\partial w} \\
& =2\left\langle f\left(x_{i}, w^{(k)}\right)-y_{i}, \frac{\partial f\left(x_{i}, w^{(k)}\right)}{\partial w}\right\rangle_{\Lambda^{(k)}}
\end{aligned}
$$

## Backpropagation

Now suppose we are using a 2 -layer model with 2 weights $f(x)=f_{2}\left(f_{1}\left(x, w_{1}\right), w_{2}\right), w_{1}, w_{2} \in \mathbb{R}$, $w=\left(w_{1}, w_{2}\right)$,

$$
\begin{array}{r}
\left.\frac{d}{d w_{2}} L\right|_{w^{(k)}}=2 \sum_{i \in \Lambda^{(k)}}\left(f_{2}\left(f_{1}\left(x_{i}, w_{1}^{(k)}\right), w_{2}^{(k)}\right)-y_{i}\right) \frac{\partial f_{2}\left(f_{1}\left(x_{i}, w_{1}^{(k)}\right), w_{2}^{(k)}\right)}{\partial w_{2}} \\
\\
=\underset{\substack{\text { tensor form }}}{ } 2\left\langle f_{2}\left(f_{1}\left(x_{i}, w_{1}^{(k)}\right), w_{2}^{(k)}\right)-y_{i}, \frac{\partial f_{2}\left(f_{1}\left(x_{i}, w_{1}^{(k)}\right), w_{2}^{(k)}\right)}{\partial w_{2}}\right\rangle_{\Lambda^{(k)}} \\
\left.\frac{d}{d w_{1}} L\right|_{w^{(k)}}=2 \sum_{i \in \Lambda^{(k)}}\left(f_{2}\left(f_{1}\left(x_{i}, w_{1}^{(k)}\right), w_{2}^{(k)}\right)-y_{i}\right) \frac{\partial f_{2}\left(f_{1}\left(x_{i}, w_{1}^{(k)}\right), w_{2}^{(k)}\right)}{\partial f_{1}} \frac{\partial f_{1}\left(x_{i}, w_{1}^{(k)}\right)}{\partial w_{1}}
\end{array}
$$

So, the first layer passes to the second layer the information $\left\{f_{1}\left(x_{i}, w_{1}^{(k)}\right)\right\}_{\Lambda^{(k)}},\left\{\frac{\partial f_{1}\left(x_{i}, w_{1}^{(k)}\right)}{\partial w_{1}}\right\}_{\Lambda^{(k)}}$

## An overview of gradient descent optimization algorithms*

Sebastian Ruder
Insight Centre for Data Analytics, NUI Galway
Aylien Ltd., Dublin ruder.sebastian@gmail.com

```
import torch.optim as optim
criterion = nn.CrossEntropyLoss()
optimizer = optim.SGD(net.parameters(), lr=0.001, momentum=0.9)
```

Gradient descent is a way to minimize an objective function $J(\theta)$ parameterized by a model's parameters $\theta \in \mathbb{R}^{d}$ by updating the parameters in the opposite direction of the gradient of the objective function $\nabla_{\theta} J(\theta)$ w.r.t. to the parameters. The learning rate $\eta$ determines the size of the steps we take to reach a (local) minimum. In other words, we follow the direction of the slope of the surface created by the objective function downhill until we reach a valley. ${ }^{5}$

Vanilla gradient descent, aka bateh gradient deseent, computes the gradient of the cost function w.r.t. to the parameters $\theta$ for the entire training dataset:

$$
\begin{equation*}
\theta=\theta-\eta \cdot \nabla_{\theta} J(\theta) \tag{1}
\end{equation*}
$$

As we need to calculate the gradients for the whole dataset to perform just one update, bateh gradient descent can be very slow and is intractable for datasets that do not fit in memory. Bateh gradient descent also does not allow us to update our model online, i.e. with new examples on-the-fly.

In code, batch gradient descent looks something like this:

```
for i in range(nb_epochs):
    params_grad = evaluate_gradient(loss_function, data, params)
    params = params - learning_rate * params_grad
```

Mini-batch gradient descent finally takes the best of both worlds and performs an update for every mini-batch of $n$ training examples:

$$
\begin{equation*}
\theta=\theta-\eta \cdot \nabla_{\theta} J\left(\theta ; x^{(i: i+n)} ; y^{(i: i+n)}\right) \tag{3}
\end{equation*}
$$

This way, it a) reduces the variance of the parameter updates, which can lead to more stable convergence; and b) can make use of highly optimized matrix optimizations common to state-of-the-art deep learning libraries that make computing the gradient w.r.t. a mini-batch very efficient. Common mini-batch sizes range between 50 and 256, but can vary for different applications. Mini-batch gradient descent is typically the algorithm of choice when training a neural network and the term SGD usually is employed also when mini-batches are used. Note: In modifications of SGD in the rest of this post, we leave out the parameters $x^{(i: i+n)} ; y^{(i: i+n)}$ for simplicity.
In code, instead of iterating over examples, we now iterate over mini-batches of size 50 :

```
for i in range(nb_epochs):
    np.random.shuffle(data)
    for batch in get_batches(data, batch_size=50):
        params_grad = evaluate_gradient(loss_function, batch, params)
        params = params - learning_rate * params_grad
```

### 4.1 Momentum

SGD has trouble navigating ravines, i.e. areas where the surface curves much more steeply in one dimension than in another [20], which are common around local optima. In these scenarios, SGD oscillates across the slopes of the ravine while only making hesitant progress along the bottom towards the local optimum as in Figure 2a.

(a) SGD without momentum

(b) SGD with momentum

Figure 2: Source: Genevieve B. Orr
Momentum [17] is a method that helps accelerate SGD in the relevant direction and dampens oscillations as can be seen in Figure 2b. It does this by adding a fraction $\gamma$ of the update vector of the past time step to the current update vector ${ }^{8}$

$$
\begin{align*}
v_{t} & =\gamma v_{t-1}+\eta \nabla_{\theta} J(\theta)  \tag{4}\\
\theta & =\theta-v_{t}
\end{align*}
$$

The momentum term $\gamma$ is usually set to 0.9 or a similar value.

## Momentum - exponential averaging of past gradients

$$
\begin{aligned}
v_{t} & =\gamma v_{t-1}+\eta \nabla_{\theta} J\left(\theta^{(t)}\right) \\
& =\gamma\left(\gamma v_{t-2}+\eta \nabla_{\theta} J\left(\theta^{(t-1)}\right)\right)+\eta \nabla_{\theta} J\left(\theta^{(t)}\right) \\
& =\gamma^{2} v_{t-2}+\gamma \eta \nabla_{\theta} J\left(\theta^{(t-1)}\right)+\eta \nabla_{\theta} J\left(\theta^{(t)}\right) \\
& \cdots \\
& =\gamma^{n} v_{t-n}+\eta\left(\gamma^{n-1} \nabla_{\theta} J\left(\theta^{(t-n+1)}\right)+\cdots+\gamma \nabla_{\theta} J\left(\theta^{(t-1)}\right)+\nabla_{\theta} J\left(\theta^{(t)}\right)\right)
\end{aligned}
$$

### 4.3 Adagrad

Adagrad [8] is an algorithm for gradient-based optimization that does just this: It adapts the learning rate to the parameters, performing larger updates for infrequent and smaller updates for frequent parameters. For this reason, it is well-suited for dealing with sparse data. Dean et al. [6] have found that Adagrad greatly improved the robustness of SGD and used it for training large-scale neural nets at Google, which - among other things - learned to recognize cats in Youtube videos ${ }^{10}$. Moreover, Pennington et al. [16] used Adagrad to train GloVe word embeddings, as infrequent words require much larger updates than frequent ones.
Previously, we performed an update for all parameters $\theta$ at once as every parameter $\theta_{i}$ used the same learning rate $\eta$. As Adagrad uses a different learning rate for every parameter $\theta_{i}$ at every time step $t$, we first show Adagrad's per-parameter update, which we then vectorize. For brevity, we set $g_{t, i}$ to be the gradient of the objective function w.r.t. to the parameter $\theta_{i}$ at time step $t$ :

$$
\begin{equation*}
g_{t, i}=\nabla_{\theta_{t}} J\left(\theta_{t, i}\right) \tag{6}
\end{equation*}
$$

The SGD update for every parameter $\theta_{i}$ at each time step $t$ then becomes:

$$
\begin{equation*}
\theta_{t+1, i}=\theta_{t, i}-\eta \cdot g_{t, i} \tag{7}
\end{equation*}
$$

In its update rule, Adagrad modifies the general learning rate $\eta$ at each time step $t$ for every parameter $\theta_{i}$ based on the past gradients that have been computed for $\theta_{i}$ :

$$
\begin{equation*}
\theta_{t+1, i}=\theta_{t, i}-\frac{\eta}{\sqrt{G_{t, i i}+\epsilon}} \cdot g_{t, i} \tag{8}
\end{equation*}
$$

$G_{t} \in \mathbb{R}^{d \times d}$ here is a diagonal matrix where each diagonal element $i, i$ is the sum of the squares of the gradients w.r.t. $\theta_{i}$ up to time step $t^{11}$, while $\epsilon$ is a smoothing term that avoids division by zero (usually on the order of $1 e-8$ ). Interestingly, without the square root operation, the algorithm performs much worse.
As $G_{t}$ contains the sum of the squares of the past gradients w.r.t. to all parameters $\theta$ along its diagonal, we can now vectorize our implementation by performing an element-wise matrix-vector multiplication $\odot$ between $G_{t}$ and $g_{t}$ :

$$
\begin{equation*}
\theta_{t+1}=\theta_{t}-\frac{\eta}{\sqrt{G_{t}+\epsilon}} \odot g_{t} \tag{9}
\end{equation*}
$$

One of Adagrad's main benefits is that it eliminates the need to manually tune the learning rate. Most implementations use a default value of 0.01 and leave it at that.

Adagrad's main weakness is its accumulation of the squared gradients in the denominator: Since every added term is positive, the accumulated sum keeps growing during training. This in turn causes the learning rate to shrink and eventually become infinitesimally small, at which point the algorithm is no longer able to acquire additional knowledge. The following algorithms aim to resolve this flaw.

### 4.6 Adam

Adaptive Moment Estimation (Adam) [10] is another method that computes adaptive learning rates for each parameter. In addition to storing an exponentially decaying average of past squared gradients $v_{t}$ like Adadelta and RMSprop, Adam also keeps an exponentially decaying average of past gradients $m_{t}$, similar to momentum:

$$
\begin{align*}
m_{t} & =\beta_{1} m_{t-1}+\left(1-\beta_{1}\right) g_{t} \\
v_{t} & =\beta_{2} v_{t-1}+\left(1-\beta_{2}\right) g_{t}^{2} \tag{19}
\end{align*}
$$

$m_{t}$ and $v_{t}$ are estimates of the first moment (the mean) and the second moment (the uncentered variance) of the gradients respectively, hence the name of the method. As $m_{t}$ and $v_{t}$ are initialized as vectors of 0 's, the authors of Adam observe that they are biased towards zero, especially during the initial time steps, and especially when the decay rates are small (i.e. $\beta_{1}$ and $\beta_{2}$ are close to 1 ).

They counteract these biases by computing bias-corrected first and second moment estimates:

$$
\begin{align*}
\hat{m}_{t} & =\frac{m_{t}}{1-\beta_{1}^{t}}  \tag{20}\\
\hat{v}_{t} & =\frac{v_{t}}{1-\beta_{2}^{t}}
\end{align*}
$$

They then use these to update the parameters just as we have seen in Adadelta and RMSprop, which yields the Adam update rule:

$$
\begin{equation*}
\theta_{t+1}=\theta_{t}-\frac{\eta}{\sqrt{\hat{v}_{t}}+\epsilon} \hat{m}_{t} \tag{21}
\end{equation*}
$$

The authors propose default values of 0.9 for $\beta_{1}, 0.999$ for $\beta_{2}$, and $10^{-8}$ for $\epsilon$. They show empirically that Adam works well in practice and compares favorably to other adaptive learning-method algorithms.
